Summary

Background: Enhanced external counterpulsation (EECP) currently is used as an outpatient therapy for patients with refractory chronic angina.

Hypothesis: We sought to determine the safety and feasibility of a portable EECP unit to treat patients with acute coronary syndrome and/or cardiogenic shock in the coronary care unit (CCU).

Methods: Ten patients with acute coronary syndrome and/or cardiogenic shock who were not considered candidates for invasive intra-aortic balloon counterpulsation (IABP) by the treating cardiologist were prospectively enrolled in this single-center study. Each patient received 2–4 one-hour EECP treatments performed at the bedside in the CCU. Anticoagulation or recent femoral access was not an exclusion criterion.

Results: The mean age was 58 ± 19 years (range 28–81), and half were women. Patients had either acute coronary syndrome alone (n = 4), cardiogenic shock alone (n = 3), or both (n = 3). The cardiac indications for study enrollment included: acute inferior wall ST-segment elevation myocardial infarction with cardiogenic shock (n = 2), non-ST-segment elevation myocardial infarction with postinfarction angina (n = 2) or heart failure (n = 1), unstable angina with refractory rest angina (n = 2), cardiogenic shock from ischemic cardiomyopathy with severe mitral regurgitation (n = 1), and cardiogenic shock from nonischemic cardiomyopathy (n = 2). No adverse events were recorded during or as a consequence of EECP therapy, including no bleeding complications, no heart failure exacerbations, and no skin breakdown. The portable EECP unit did not interfere with ongoing critical care nursing.

Conclusions: EECP is safe and feasible for acute bedside therapy of critically ill patients with acute coronary syndrome and/or cardiogenic shock who are not candidates for IABP.

Key words: coronary artery disease, heart failure, external counterpulsation, acute coronary syndrome, cardiogenic shock

Clin. Cardiol. 2007; 30: 223–228.

Introduction

In current clinical practice, enhanced external counterpulsation (EECP) is used for the outpatient treatment of refractory angina and heart failure. EECP has an antianginal effect in outpatients with exercise-induced myocardial ischemia.[1–5] EECP increases diastolic aortic pressure, thereby increasing coronary artery perfusion. Cuff deflation at the onset of systole decreases left ventricular afterload by systolic unloading.[6] These acute hemodynamic effects achieved with EECP are comparable to those with invasive intra-aortic balloon counterpulsation (IABP).[6]

While the use of IABP in acute coronary syndromes (ACS) and cardiogenic shock is well-established, there are situations when its application is limited due to

the potential complications of lower extremity ischemia, bleeding, and infection.[7,8] For patients with IABP contraindications, EECP presents a potential noninvasive method for increasing coronary perfusion and ventricular unloading.

While early EECP devices using a hydraulic water compression system showed limited efficacy for cardiogenic shock[9–12] and acute myocardial infarction,[13] there have been no studies using the pneumatic EECP devices in these clinical situations. This pilot study sought to determine the safety and feasibility of a portable EECP device to treat acutely ill patients in the coronary care unit (CCU) with ACS and/or cardiogenic shock.

Methods

Patients

This single-center study enrolled adult CCU patients admitted with ACS (Braunwald class IIIB/C unstable angina,[14] non-ST-segment elevation myocardial infarction, or ST-segment elevation myocardial infarction) and/or cardiogenic shock who were not candidates for IABP by the treating cardiology team. Exclusion criteria included severe aortic insufficiency, supraventicular tachyarrhythmias, thrombophlebitis, active femoral site bleeding or hematoma, and uncontrolled hypertension (>180/100 mmHg). Recent femoral vascular access and decompensated heart failure if the patient was intubated were not exclusion criteria. Patients or the surrogate decision-maker gave written informed consent prior to EECP, and the protocol was approved by the Committee on Human Research.

Study Procedures

EECP treatment was performed in the CCU (TS3 portable prototype model, Vasomedical, Inc., Westbury, NY). Patients received 2–4 one-hour EECP treatments over 24 h. Three sets of disposable lower-extremity pneumatic cuffs were connected by air hoses to the portable compressor unit (Fig. 1) in the CCU bed. The EECP device sequentially inflated the cuffs timed with the patient's cardiac cycle measured by electrocardiography. At the onset of systole, compressed air is released to reduce systolic aortic pressure. Counterpulsation was performed at cuff inflation pressures ranging from 80 to 300 mmHg. Noninvasive finger plethysmography was used to monitor the arterial waveforms. If systemic arterial and pulmonary artery catheters were used clinically, hemodynamic data was recorded before, during, and after each EECP treatment. Urine output prior to and during EECP was assessed using a Foley catheter. Patients were asked to report the severity of chest pain and dyspnea on a 0–10 scale before and during each EECP treatment. The cuff inflation pressure was started at low pressure (80 mmHg) and increased gradually over the 1-h treatment course as tolerated. Monitoring of the femoral access sites for vascular injury was performed.

Statistical Analysis

Continuous variables are presented as means standard deviations. Paired t-tests were used to compare continuous variables prior to and 30-min after initiation of EECP. Two-tailed probability (p) values <0.05 were considered significant. Statistical computations were performed using Stata version 9.2 (Stata Corporation, College Station, TX).

Results

Baseline Characteristics

Ten patients were enrolled (Table 1). The mean age was 58 ± 19 years (range 28–81), and half were women. Patients had either ACS alone (n = 4), cardiogenic shock alone (n = 3), or both (n = 3). The cardiac indications for study enrollment included: acute inferior wall ST-segment elevation myocardial infarction with cardiogenic shock (n = 2), non-ST-segment elevation myocardial infarction with postinfarction angina (n = 2) or heart failure (n = 1), class IIIB unstable angina with refractory rest angina (n = 2), cardiogenic shock from ischemic cardiomyopathy with severe mitral regurgitation (n = 1), and cardiogenic shock from nonischemic cardiomyopathy (n = 2). Two subjects had severe mitral regurgitation. Two others were intubated prior to study enrollment, and were continued on mechanical ventilation during the study period.

The decision not to treat the patients with IABP was made at the treating physicians' discretion. Reasons for selecting patients included preference for a noninvasive approach (n = 6), severe iliac tortuosity (n = 1), abdominal aortic ulcer (n = 1), recent abdominal aortic surgery (n = 1), and concern for infection one day following biventricular pacemaker implantation (n = 1).

Seven patients had femoral arterial access within 48 h of EECP. Four patients had current femoral arterial and/or femoral venous sheaths in place during EECP treatment.

EECP Therapy

Patients received an average of 2.5 ± 0.7 h of EECP therapy (range 2–4 h; Table 2). Patients were treated with antiplatelet and antithrombin agents including unfractionated intravenous heparin (n = 7), glycoprotein IIB/IIIA receptor blockers (n = 5), aspirin (n = 8), and clopidogrel (n = 7; Table 2). Arterial pressure was measured invasively in four patients, and noninvasively in sixs patients. During treatment, there was a significant increase in mean arterial pressure measured 30-min after starting EECP compared to baseline ($p = 0.0002$;

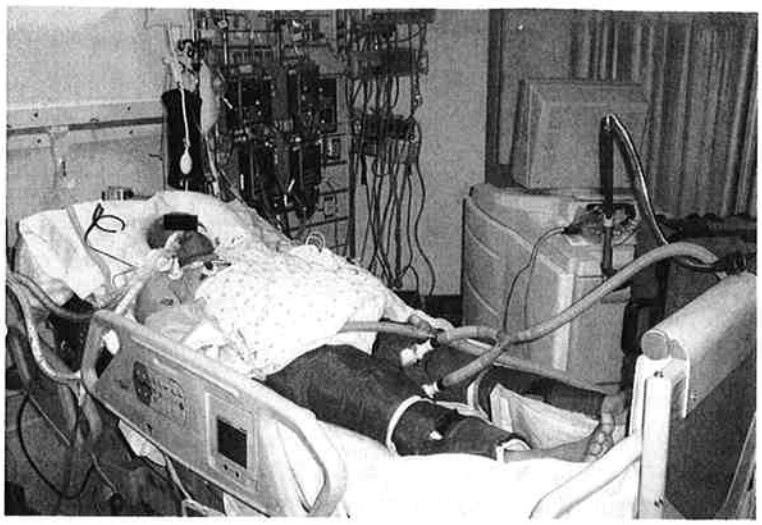

FIG. 1 Portable enhanced external counterpulsation on a critically ill patient in the coronary care unit. This patient remained in cardiogenic shock after successful right coronary artery stenting for acute inferior ST-segment elevation myocardial infarction. An intra-aortic balloon pump was not possible due to severe bilateral iliac artery tortuosity.

Table 3). There were no significant changes in heart rate, pulse oximetry, or urine output. While there was no significant change in chest pain severity, the severity of dyspnea improved during EECP ($p = 0.036$). No EECP-related adverse events were recorded during or as a consequence of EECP therapy, including no bleeding complications, no heart failure exacerbations, and no skin breakdown from the pneumatic cuffs. Potential concerns such as excessive noise from the air compressor units, moving the TS3 device into the CCU rooms, or interference with ongoing critical care nursing did not occur during this study.

EECP in Unstable Angina

Patient 4 was an 81-year-old woman hospitalized with Braunwald class IIIB unstable angina. Angiography showed occlusion of all native coronary arteries and all grafts from her two prior coronary bypass surgeries. She was not a candidate for further coronary revascularization, and was treated with intravenous antianginal agents with continued rest angina in the CCU. After two one-hour EECP treatments, the patient's angina appeared less frequent and less severe (from 8/10 down to 3/10). The patient was discharged with the plan to continue EECP as an outpatient.

EECP in Acute Myocardial Infarction

Patient 2 was a 45-year-old man who presented with an acute non-ST-elevation myocardial infarction. Urgent coronary angiography revealed critical stenoses of the left main, left anterior descending, and right coronary arteries with thrombolysis in myocardial infarction (TIMI) III flow. He was referred for coronary artery bypass grafting, but the timing of surgery was delayed due to the patient's clopidogrel exposure. He was admitted to the CCU where he developed recurrent

angina. His angina improved after treatment with EECP therapy.

Patient 5 was a 76-year-old man with history of three-vessel coronary artery disease and diabetes who underwent EECP in the CCU 16 h after right coronary artery stenting for acute inferior ST-segment elevation myocardial infarction (Fig. 1). The patient remained in cardiogenic shock from extensive right ventricular infarction, and was hypotensive despite dopamine and dobutamine. The patient did not receive an IABP due to severe bilateral iliac artery tortuosity. He was discharged from the hospital on day 6, and did well at 8-month follow-up.

EECP in Cardiogenic Shock

Patient 6 was a 32-year-old man with nonischemic cardiomyopathy with a left ventricular ejection fraction of 21%. One day prior to enrollment, he underwent biventricular pacemaker defibrillator implantation. Shortly thereafter, he was intubated for pulmonary edema. He remained hypotensive with poor urine output despite treatment with intravenous furosemide, dopamine, dobutamine, and norepinephrine. He started EECP 16 h after intubation, and subsequently his urine output increased from 20 cc/h to 100 cc/h, beginning 30-min after initiation of EECP. He was extubated 3 days later, but died two weeks later from a respiratory arrest. Patient 8 had low urine output (20 cc/h) prior to EECP. This patient had cardiogenic shock from an ischemic cardiomyopathy and severe mitral regurgitation. This subject had no improvement in urine output during EECP.

Patient 9 was a 28-year-old woman on intravenous milrinone and furosemide awaiting heart transplantation for dilated cardiomyopathy. She tolerated EECP well

FIG. 2 Radial arterial tracing from patient 9 at baseline (a) and during enhanced external counterpulsation at a cuff inflation pressure of 300 mmHg (b). The patient is a 28-year-old woman on intravenous milrinone and furosemide who was awaiting heart transplantation for dilated cardiomyopathy.

with improvement in her hemodynamics (Fig. 2). She underwent orthotopic heart transplantation and was doing well at 9-month follow-up. Both patients with severe mitral regurgitation reported an improvement in their rest dyspnea during EECP.

Discussion

In current practice, EECP is limited to the outpatient management of refractory angina and heart failure. EECP systems are essentially fixed in place and cannot routinely be transported. This pilot study demonstrated the safety and feasibility of a portable prototype EECP system to provide bedside treatment to critically ill CCU patients. Observations suggested that acute inpatient EECP therapy may improve cardiovascular performance and possibly clinical outcomes in patients with ACS and/or cardiogenic shock.

Research regarding the hemodynamic and clinical effects of external counterpulsation began in the 1960s using hydraulic-driven, water-filled compression chambers. Soroff first applied external counterpulsation in man.[9,10] Among 20 patients with cardiogenic shock treated with external counterpulsation, the mortality rate of 65% was reported to be lower than historical rates for IABP.[11]

External counterpulsation prevented the hypotension caused by nitroprusside vasodilator therapy, providing left ventricular systolic unloading pharmacologically while maintaining coronary perfusion by external counterpulsation.[15] In a multicenter study, 258 acute myocardial infarction patients were randomized to external counterpulsation within 24 h of presentation or usual care.[13] External counterpulsation patients had a trend toward lower hospital mortality rate (8.4%) compared with controls (14.7%; $p = 0.12$). Counterpulsation patients had lower rates of recurrent angina, heart failure, and ventricular fibrillation.

There were limitations of early external counterpulsation devices.[9–13,15] The leg compression bags were not sufficiently powerful to provide effective systolic unloading. Studies of cardiac metabolism showed that IABP decreased myocardial oxygen consumption, while external counterpulsation increased consumption. In studies measuring coronary sinus blood flow during atrial pacing, early external counterpulsation devices had no acute beneficial metabolic or hemodynamic effects.[16,17]

The modern pneumatic cuff EECP system augments intracoronary pressure and flow.[6] Improving coronary perfusion pressure in addition to left ventricular systolic unloading makes EECP a potentially useful hemodynamic assist device. A recent trial showed that EECP was superior to medical therapy alone in stable outpatients with left ventricular systolic dysfunction, resulting in improved exercise tolerance, heart failure class, and quality of life.[18] In two of our patients with severe mitral regurgitation, patient-reported severity of dyspnea improved during EECP. In this pilot study, we observed no harmful effect from increased venous return in patients with heart failure.

This study is limited by its small size and single-center design. As a safety and feasibility study, it was not designed to evaluate the efficacy of portable EECP compared to other treatments. We could not report changes in aortic and diastolic arterial pressure because six of the ten subjects had noninvasive measures of systemic pressure. The subjective measures of chest pain and dyspnea severity were aimed at assessing safety.

In conclusion, portable EECP is a safe and feasible treatment for critically ill patients suffering from acute coronary syndrome and/or cardiogenic shock who are not candidates for IABP therapy. The acute hemodynamic effects of increased coronary perfusion and left ventricular systolic unloading with EECP are favorable for these patient groups, suggesting that acute EECP may result in improved clinical outcomes in those with acute coronary syndrome and/or cardiogenic shock.
